The Supplementary Information contains details on the methods used in the microcosm study and the corresponding results and discussion. Five tables are also included which detail the instrumental precision and accuracy, method performance data, drug degradation rates and half-lives in microcosm studies, replicate data of fish analysis and dissolved oxygen, pH, and temperature data from microcosms.

1. Materials and methods

1.1. Microcosm study

The water sample used in the microcosm study was kept cool (but not frozen) for 72 hours before use. Four 2 L vessels of water were prepared in borosilicate Duran bottles. Two vessels were treated with 1 g L⁻¹ NaN₃ to inhibit microbial activity (abiotic conditions). One biotic and one abiotic vessel were kept in a cold room maintained at 4 °C in the dark. The other biotic and abiotic vessels were kept in an All-Round Toxkit Incubator (Microbiotests, Gent, Belgium) under light provided by light emitting diode lamps. The contents of the various vessels were continually mixed on a magnetic stirrer. This achieved a water temperature of 8 °C in all vessels (Table S5). Once this temperature was reached, each vessel was spiked at 1 µg L⁻¹ with individual drug enantiomers using 100 µL of a 20 µg mL⁻¹ mixed analyte solution in 50:50 water: methanol (achiral analytes were at 40 µg mL⁻¹ and were therefore spiked at 2 µg L⁻¹). Each microcosm was sampled (25 mL) in triplicate at the following intervals: 0, 0.33, 1, 1.33, 4, 5, 7, 8, 11 and 14 days. Samples were then extracted as described in Section 2.3.1. Drug degradation was fitted to the first-order exponential degradation model using eq (1):

$$C_t = C_0 e^{-kt} \quad (1)$$

Here, C_t is the drug concentration at time t (days (d)) and C_0 is the drug concentration at the start of the study (0 d), and k is the degradation rate constant (1/d). Drug half-life ($t_{1/2}$) was calculated according to eq (2):

$$t_{1/2} = \frac{\ln(2)}{k} \quad (2)$$

Water temperature, pH, and dissolved oxygen concentration were also monitored (Table S5).

Method detection limits (MDLs) and method quantitation limits (MQLs) of the entire SPE-enantioselective LC-MS/MS method was calculated using Eq (3) and (4)¹:

$$MDL = \frac{(IDL \times 100)}{(Rec \times CF)} \quad (3)$$

$$MQL = \frac{(IQL \times 100)}{(Rec \times CF)} \quad (4)$$

Here *IDL* is the instrument detection limit (ng L^{-1}), *IQL* is the instrument quantitation limit (ng L^{-1}). These were the lowest concentrations which gave a signal to noise ratio of ≥ 3 and ≥ 10 respectively. *Rec* is the recovery from spiked matrix (%) and *CF* is the SPE sample concentration factor.

2. Results and discussion

2.1. Microcosm study

Under biotic conditions paracetamol had a $t_{1/2}$ value of 31.7 and 5.5 days in light and dark conditions respectively (Table S3). A cloudy appearance developed in the light microcosm after a few days. This was not observed in the dark biotic microcosm suggesting differences in the changes in the microbial community under light and dark conditions. This could account for differences in degradation observed. In abiotic microcosms no degradation of paracetamol or indeed any of the drugs was observed under either light or dark conditions. Microcosm studies by Benotti and Brownawell² found paracetamol $t_{1/2}$ values in the range 1.2-11.0 days in estuarine and coastal waters from inside and outside of Jamaica Bay, New York, USA, albeit under slightly different conditions (15 °C and aeration). The mean dissolved oxygen concentrations in this study, provided by continuous mixing of the water, were 11.2-11.6 mg L^{-1} at 8 °C.

No degradation of carbamazepine, carbamazepine-10,11-epoxide, caffeine, or (-)-cotinine was observed during 14 days under light or dark conditions (Table S3). Carbamazepine is well-known for its recalcitrant nature in the environment, including marine waters.^{2,3} Cotinine has also previously been found to be resistant to degradation in marine water microcosms.² However, Benotti and Brownawell² found caffeine $t_{1/2}$ values to range from 3.5 days to >100 days depending on the sampling location of the water.

Most of the studied chiral drugs, including amphetamine, methamphetamine, atenolol, sotalol, bisoprolol, acebutolol, metoprolol, venlafaxine and desmethylvenlafaxine, did not show any degradation (or enantioselectivity) in biotic microcosms (Table S3). On the other hand, both chlorpheniramine and propranolol degraded in the light microcosm, but without enantioselective changes. Interestingly, the degradation of chlorpheniramine was lower in the dark microcosm and no

degradation of propranolol was noted (Table S3). This is opposite to what was observed for paracetamol which exhibited greater degradation in the dark microcosm.

Both fluoxetine and citalopram degraded enantioselectively in the light microcosm (Table S3). The $t_{1/2}$ values of *S*(+)-fluoxetine and *R*(-)-fluoxetine were 10.4 and 19.1 days, respectively. Previous research has found fluoxetine to be susceptible to degradation in marine waters with $t_{1/2}$ values ranging from 5.9 to 9.8 days.² The initial EF value of 0.51 reduced to 0.37 over 14 days due to the slower degradation of *R*(-)-fluoxetine. This follows the same enantioselectivity of fluoxetine observed in activated sludge microcosms.^{4,5} On the other hand, enrichment of *S*(+)-fluoxetine has been observed in freshwater microcosms.⁵ This demonstrates that enantiomer enrichment can proceed in either direction depending on the environmental compartment or associated microbial community. However, the microcosm data could not be compared to environmental concentrations of fluoxetine in the Clyde Estuary owing to fluoxetine being present below the MQL in the estuarine waters (Table 1). Nevertheless, our study is the first to demonstrate the enantioselective degradation of fluoxetine or indeed any drug in estuarine water.

Citalopram degradation was slower with no appreciable degradation of *R*(-)-citalopram observed. The $t_{1/2}$ value of *S*(+)-citalopram was 37.1 days (Table S3). The initial EF value of 0.50 reduced to 0.44 over 14 days. A reduction in EF has previously been observed in activated sludge microcosms, however in freshwater microcosms no enantioselectivity was observed.⁵ In the monitoring study of the Clyde Estuary, no clear change in citalopram EF was observed down the estuary. It is considered that the enantioselective changes observed within the microcosm studies were too slow to have an appreciable effect on citalopram EF values within the estuary. However, it should be noted that the findings of the microcosm and estuary monitoring study will not be directly comparable as the estuary will be subject to other wastewater inputs between sampling locations that could influence the EF values.
