Parametric Analysis of Wax Printing Technique for Fabricating Microfluidic Paper-Based Analytic Devices (μ PAD) for Milk Adulteration Analysis

Abstract

Accurate prediction of hydrophobic-hydrophilic channel barriers is essential in fabrication of paper based microfluidic devices. This research presents a detailed parametric analysis of wax printing technique for fabricating μ PADs. Utilizing commonly used Grade 1 filter paper, experimental results show that the wax spreading in the paper porous structure depends on the initially deposited wax line thickness, a threshold melting temperature and melting time. Initial width of the printed line has a linear relationship with the final width of the barrier; however, a less pronounced effect of temperature was observed. Based on the spreading behavior of the molten wax at different parameters, a generalized regression model has been developed and validated experimentally. The developed model accurately predicts wax spreading in Whatman filter paper paper: a non-uniform distribution of pores and fibers. Finally, tests were carried out for calorimetric detection of commonly used adulterants present in milk samples.

Keywords

Paper based, microfluidics, fabrication, wax printing, analytical devices, milk adulterants

Symbols

L	Average wax spreading from the edges of printed line	F_{HC}	Final Hydrophilic channel width
I	Width of printed line	I_{HC}	Initial Hydrophilic channel width
T	Melting temperature	D	Pore size
t	Melting time	Γ	Surface tension
η	Viscosity	μm	Micrometer
ESI	Electronic supplementary Information		

1 Introduction

Paper based microfluidics is a broad group of analytical devices (μ PADs) that makes use of complex biochemical samples containing macromolecules, proteins, nucleic acids, toxins, cells or pathogens for analysis. These devices have significant potential for use in diverse application areas including point of care diagnostics, environmental regulations and food quality monitoring [1]. In recent years, μ PADs have emerged as a research area of interest for detection and diagnosis in many applications because of their simple fabrication, low cost, flexibility, user friendly functioning [2-4]. Properties like good biological compatibility, strong capillarity, ease of fabrication, disposability and easy availability of μ PADs make them unique, when compared to conventional devices made of polymer and/or glass substrates [5-7].

Various techniques used for patterning paper includes wax printing [8, 9] wax screen printing [10, 11], paper cutting[12], inkjet printing[13-15] photolithography[3], wax dipping [16], analogue plotting[17], etching[18], plasma treatment [19, 20] and laser treatment [21]. The hydrophilic-hydrophobic microchannel contrast of the paper network makes these devices suitable for handling small volumes of fluid for quantitative analysis of many potential applications in healthcare, medicine, quality control and environmental monitoring.

Carrilho *et al.* [8] in 2009 introduced an inexpensive, fast and efficient process of wax printing for patterning paper-based microfluidic devices in less than 5 minutes. A simple equation based on well-developed Washburn's equation was presented to predict the wax spreading (L) and width of the hydrophobic barriers (W_B) for initially printed line width (W_P).

$$W_B = W_P + 2L \quad (1)$$

$$L = (\gamma Dt / 4\eta)^{1/2} \quad (2)$$

This model proposes that the wax spreading is proportional to square root of time. Dungechai *et al.* [10] applied wax screen printing method and produced paper microfluidic devices on Grade 1 filter paper. The final width of the hydrophobic barriers was related to the wax spreading in the paper (predicted from Washburn equation) indicated by a linear equation. Renault *et al.* [22] studied wax transport in Whatman Grade 1 filter paper and 3MM chromatography paper, and the resulting final width of the barrier was also predicted by Washburn's equation. Zhong *et al.* [23] investigated different paper material and wax types for fabricating optimal μ PAD device and applied Washburn's equation to study the mechanics of fluid flow in the hydrophilic channel. Lu *et al.* [24] used three different methods to pattern paper using wax and performed bioassays. The resulting width of the final hydrophobic barrier was estimated from the difference between original printed line and the final spread line after heating step. One of the biggest challenges of the microfluidic research today is the precise control of reagents within the μ PAD device which require an accurate patterning method. To develop an accurate paper-based device by a wax printing technique, an effective model is required to accurately predict the spreading of wax in the paper. This will enable prediction of the channel/ barrier final dimensions for guiding the fluidic flow within the paper network. Many researchers have proposed Washburn equation for this purpose; however, one common limitation of the Washburn's model is the approximation of paper fiber structure as a bundle of capillaries assuming the representative pore size of the paper as the capillary radius (D). Whereas, on the micro scale, the paper has a highly complex fibrous structure with interfiber pores and intra-fiber pores exhibiting a large pore size distribution within the paper surface [25]. Hence, assuming the representative pore size of the paper as capillary radius results in inaccuracy in predicting the wax spreading in the paper. In addition, the Washburn's equation can only be applied to capillary flow under constant driving pressure (infinite reservoir), during the capillary flow process [26]. However, wax spreading encounters significant pressure change as the wax spreads in the pores of the paper with a limited volume of wax deposited on its surface during the printing process.

This research focuses on wax printing method due to its simplicity i.e. using solid wax-based ink printer and a hot plate. The presented method eliminates the use of the clean room, UV lamps, organic solvent or other sophisticated instrumentation used in other methods [9]. In this work we performed a systematic series of experiments to observe the spreading of molten wax in the paper at varying temperature, initial deposited wax and different time. A regression model was developed which relates these parameters to the final achieved hydrophobic barrier width (channel dimensions). This study also employed μ PAD-based analytical device for the detection of commonly used adulterants present in milk samples. Tests were carried out for neutralizers, urea and detergents in milk samples. In order to check the functionality of device, adulterants were intentionally added to the sample. Specific reagents were used for particular reactions. These particular tests and the composition of reagents were based on the specific chemical reactions [27].

2 Materials and methods

2.1 Materials

The Whatman Grade 1 filter paper available in sheets of 46 cm \times 570 cm were chosen as substrate material for fabricating μ PAD. The desired patterns were first drawn using AutoCAD where the initially printed line thickness was varied from 100 μ m to 900 μ m. These patterns were then printed using Xerox ColorQube 8580 Printer. The thickness of the initially printed line patterns for each set were checked in the microscope before keeping on the hot plate. The reproducibility of the device is highly dependent on the initial printed line width and temperature applied for wax spreading. These printers utilize solid wax based ink composed of hydrocarbons

for printing [28]. To provide a uniformly heated surface, we used an analogue hot plate and a constant temperature of the plate was maintained using IR thermometer. The thickness of lines before and after spreading was measured using an optical microscope. Figure 1 shows schematics of the printing of μ PAD.

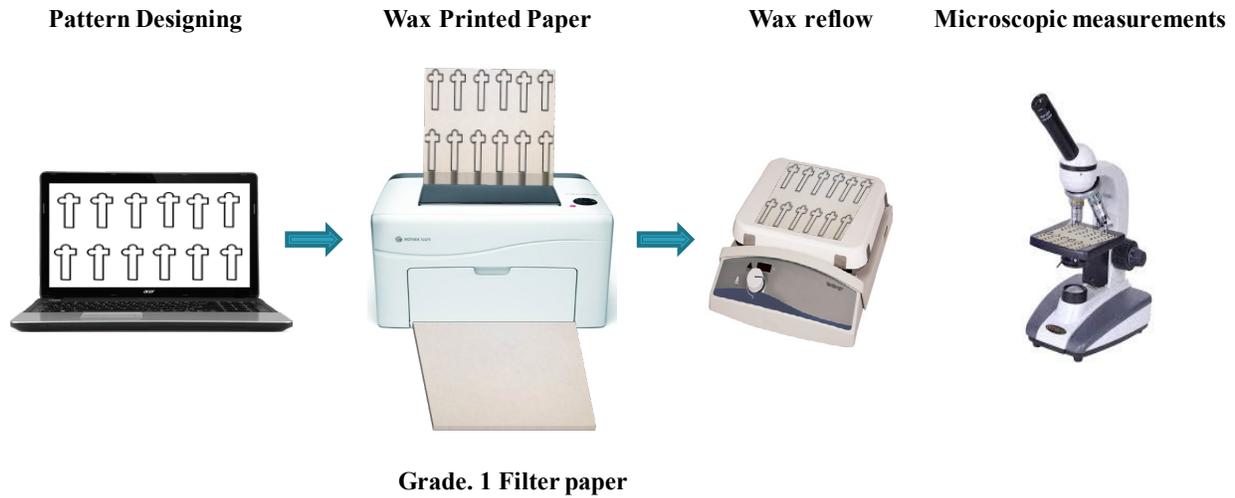

Fig. 1 Overview of wax printing technique for fabricating paper microfluidic device

2.2 Design of experiments

A series of lines of different widths were printed on filter paper, and the resulting final width of the lines was investigated at four different temperatures. Table 1 shows the range of initial printed width, time and temperature for experimentation. The wax spreading for all temperature sets were measured after five seconds interval until complete spreading of the initially printed wax on paper.

Table. 1 Experimental details and parameters

Sr. #	Parameters	Range/Value
1	Initial printed width	100 μm , 200 μm , 300 μm , 400 μm , 500 μm , 600 μm , 700 μm , 800 μm , 900 μm .
2	Time	Reading after every 5 seconds till stability.
3	Temperature	90 $^{\circ}\text{C}$, 110 $^{\circ}\text{C}$, 130 $^{\circ}\text{C}$, 150 $^{\circ}\text{C}$.

2.3 Measurement of wax spreading in paper

The printed lines, after placing on hot plate, were studied after five seconds interval to observe the change in the width of the line until complete spreading was achieved. The printed lines were studied for the time required for complete melting at different temperatures. Figure 2 shows measurement on a 900 μm printed wax line before and after spreading (at 90 $^{\circ}\text{C}$). Three readings were taken for each line and the results were averaged.

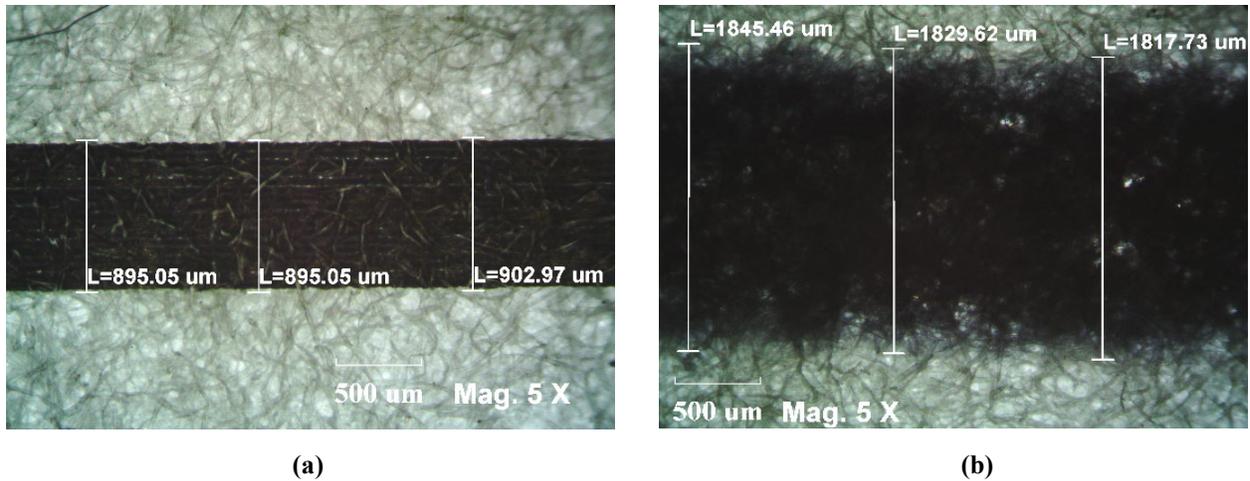

Fig. 2 Optical microscope image of 900µm initial wax line (a) before spreading, (b) after complete spreading at 90°C

3 Results and discussions

3.1 Experimental conditions study

3.1.1 The effect of temperature on the melting time

A series of lines printed on paper ranging from 100 µm to 900 µm were studied for the optimal time required to complete the spreading of wax in the paper. The maximum time needed for spreading of wax in the paper was recorded at four different temperatures for these printed lines. Spreading time for lines of width 100 µm, 300 µm, 600 µm and 900 µm at four temperatures (90 °C, 110 °C, 130 °C and 150 °C) is shown in ESI Figure 1 (a-d). It was observed that there is dominant effect of melting temperature on the total time required for complete spreading such that at high temperature the wax spreads quickly as compared to lower temperatures. Finally, the total fabrication time for devices at temperatures 90 °C, 110 °C, 130 °C and 150 °C resulted in 240 secs, 120 secs, 95 secs and 70 secs respectively. Figure 3 shows that the wax spreading time within the paper reduces as the temperature is increased from 90 °C to 150 °C.

Tables presents optical microscope images of the spreading of wax printed lines (100, 300 and 900µm) at 90 °C and 150 °C and at different time intervals. At higher temperature of the hot plate, the wax spreading within the paper was quick compared to the one at lower temperatures. (ESI Table. 1 and 2)

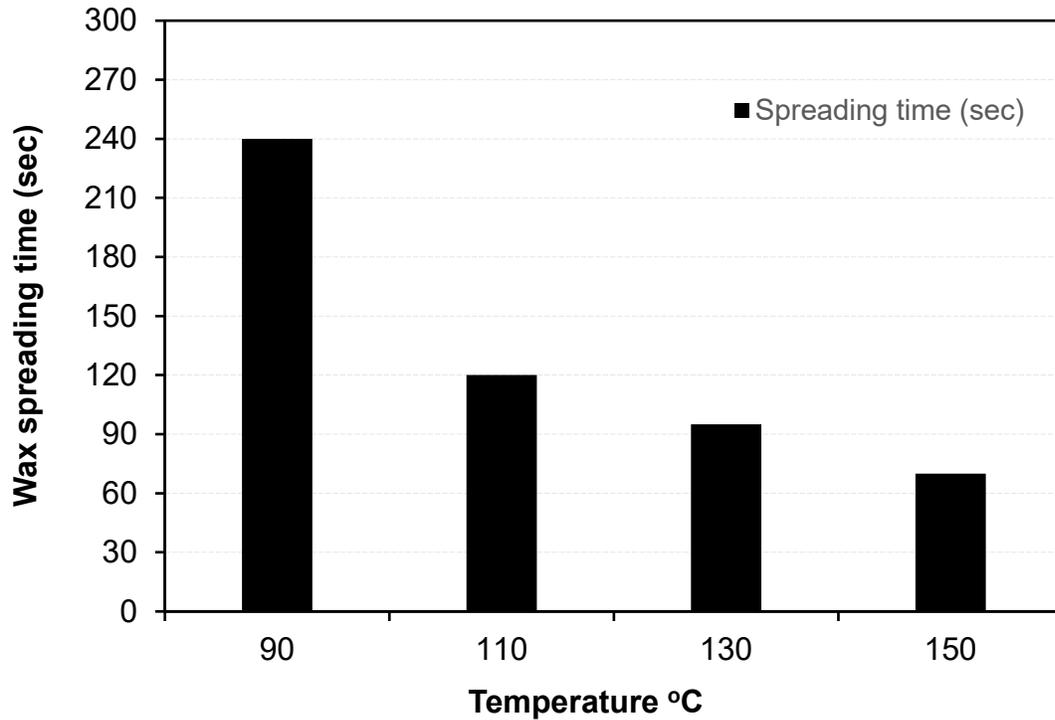

Fig. 3 Effect of temperature on spreading time at four different temperatures

3.1.2 Effect of temperature on the spreading of wax in paper

Figure 4 shows the change in final width of the line at four different temperatures for printed lines 100 μm , 300 μm , 600 μm and 900 μm at four temperatures (90 °C, 110 °C, 130 °C and 150 °C). The results shows that the wax spreads very rapidly in the start of the spreading process as the change from solid phase to liquid phase occurs (first 15 seconds of melting) then it keeps on spreading linearly until all the deposited wax fill the capillaries in the paper (ESI - Figure 2 (a-d)). The increase in the width of the barriers at higher temperature can be explained by taking into account the change in viscosity of wax as the temperature changes, as shown in Figure 5. At higher temperatures (above 100°C), viscosity of the molten wax is low and makes it flow easily within the capillaries as compared to lower temperatures (90°C). It can also be observed that for temperature above 100C, there is very less change in the viscosity of the wax, which results in minimal change in the final line width at these temperatures.

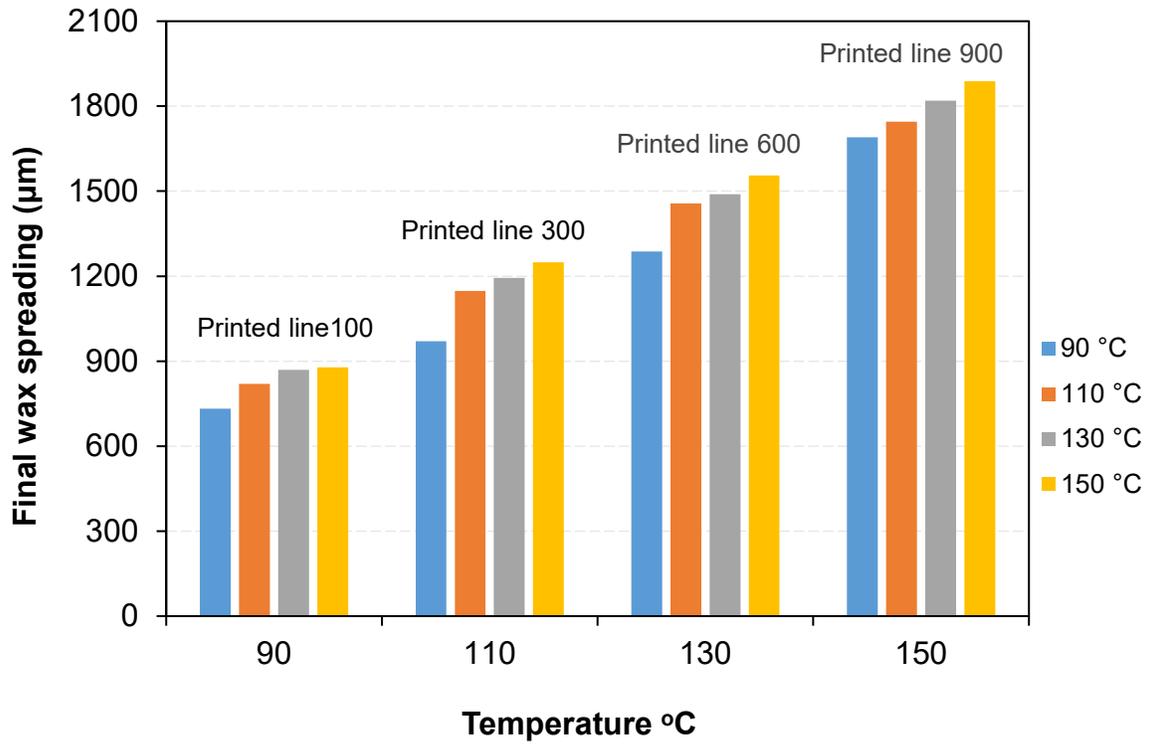

Fig. 4 Effect of temperature on the final width of the printed line

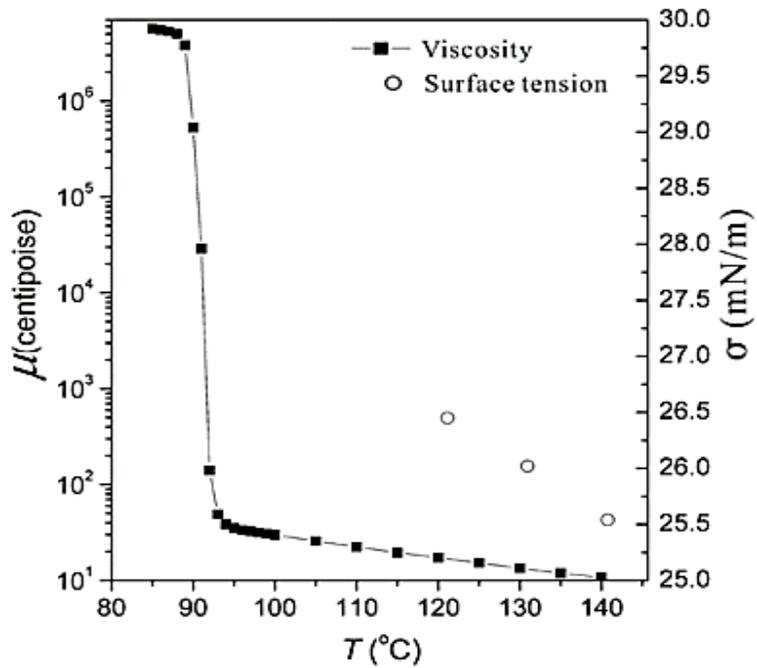

Fig. 5 Viscosity and surface tension of solid ink with varying temperature [29]

3.1.3 Effect of initially printed line width on the final wax spreading

Different initial width lines 100 μm to 900 μm were printed on filter paper and studied for its effect on the final width of the hydrophobic barrier at four different temperatures 90 $^{\circ}\text{C}$ to 150 $^{\circ}\text{C}$ (Table 1). Initial width of the printed line (Figure 6) has a significant effect on the final width of the barrier; however, varying temperature (beyond 90 $^{\circ}\text{C}$) has almost negligible effect. Lines with greater initial thicknesses have a substantial amount of deposited wax, which aids the spreading thus achieving larger final width. The results obtained shows a linear relationship between the initial printed width and final width of the barrier.

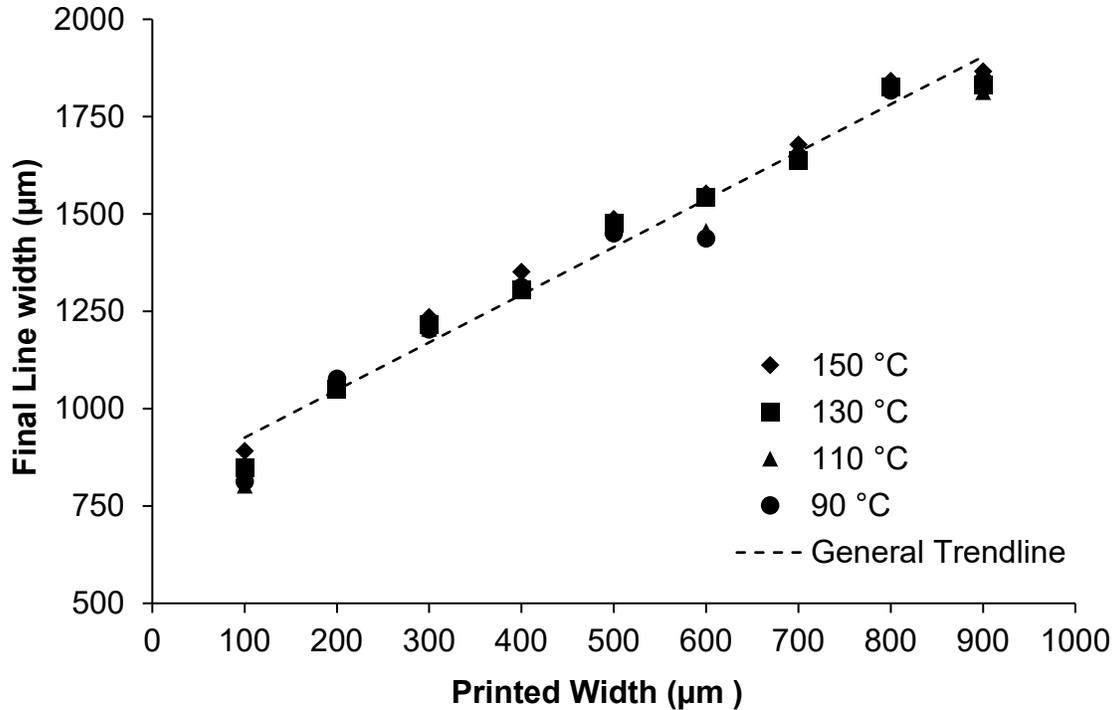

Fig. 6 Width of the wax hydrophobic barrier (line) at temperatures 90 $^{\circ}\text{C}$, 110 $^{\circ}\text{C}$, 130 $^{\circ}\text{C}$ and 150 $^{\circ}\text{C}$ after complete spreading

According to the Washburn equation [20], the paper fiber structure is considered as a bundle of capillaries formed by an alignment of pores. However, selecting a representative pore size of the paper as the capillary radius is not a true representation of the pore structure of the paper. Figure 7 shows SEM images of the filter paper with large pore size distribution. A key observation from the SEM micrograph is that the microstructure of paper cannot be accurately approximated as a bundle of cylindrical capillaries, especially considering the practical challenge of measurements of capillary radius from the paper. Also, the Washburn equation applies only to constant pressure capillary flow for unlimited fluid reservoir, whereas, in wax printing, a limited amount is deposited on the paper. The wetting behavior of pores in the paper (Figure 8) also confirms the difference between assumptions of Washburn model for spreading of fluid and actual spreading of wax in the filter paper, where after complete spreading of wax, there is no wax reservoir left on the surface of the paper.

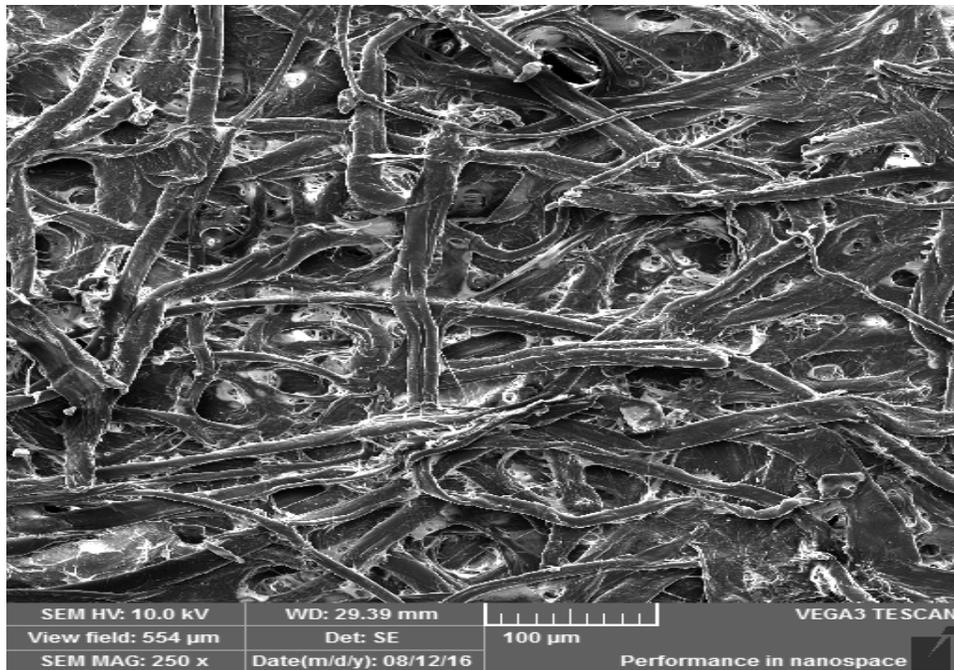

Fig. 7 SEM image of the filter paper showing pores and fiber arrangement

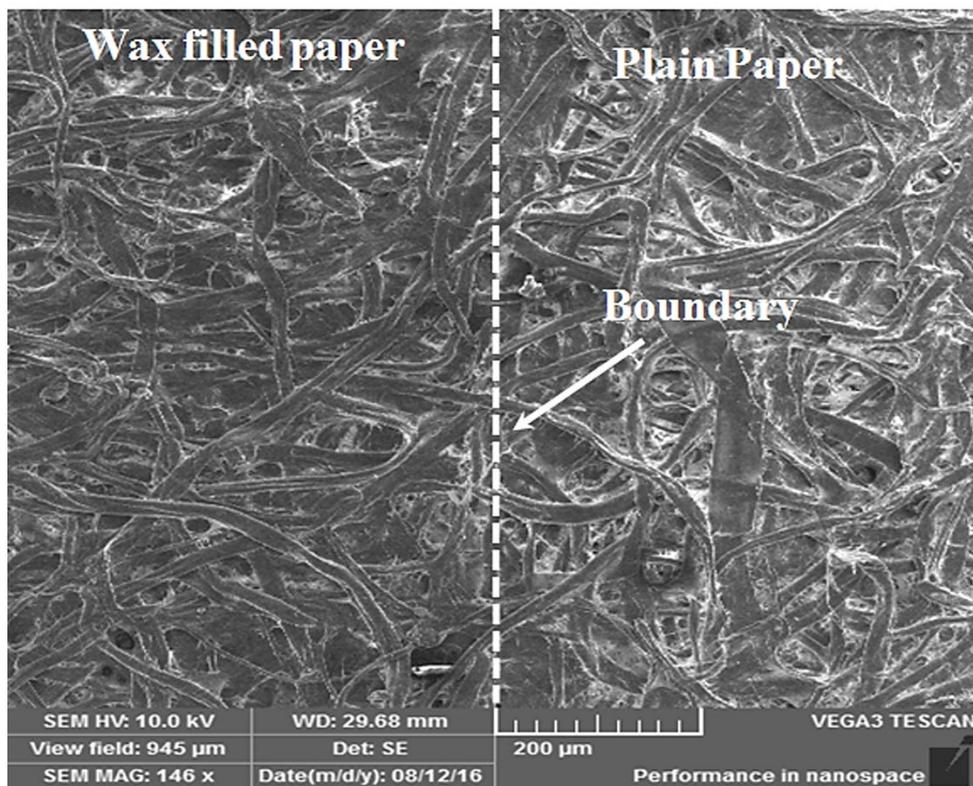

Fig. 8 SEM image of the barrier boundary showing connected pores filled with wax (left side) and plain paper (right side)

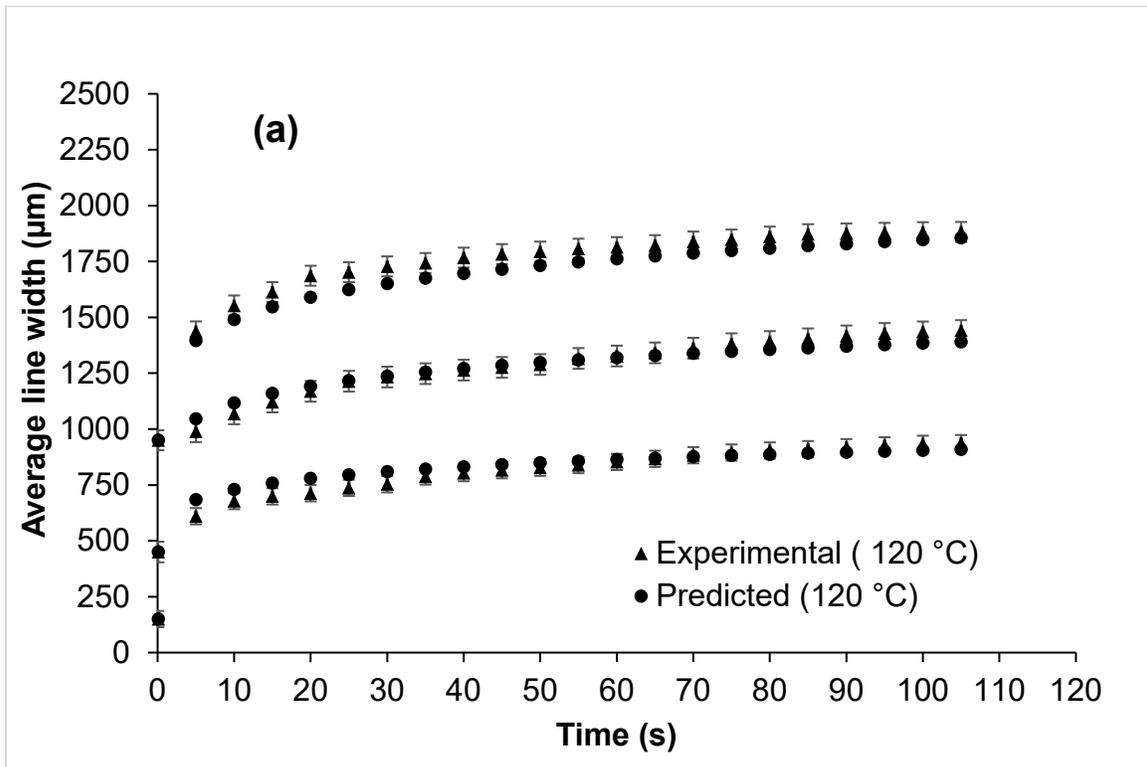

of images of the devices fabricated. The Final width of the hydrophilic channel (F_{HC}) after fabrication is obtained from equation 4 and 5, where I_{WC} is the initial width of the channel before heating step, and L is the final spreading of the printed wax line as shown in Figure 9.

$$F_{HC} = I_{WC} - L \quad (4)$$

And $L = Y - I \quad (5)$

3.2.2 Validation of the regression model

The suggested regression model was validated for additional printed lines of width 150 μm , 350 μm , and 850 μm at temperatures 120 $^{\circ}\text{C}$ and 140 $^{\circ}\text{C}$ experimentally and was studied for the complete melting time. A maximum 8 % error was observed in experimental and predicted data from the model. The experimental and predicted data plotted in Figure 10 Shows that the model can best predict the final width of the hydrophobic barrier, by setting all the parameters in the equation. (3). Furthermore, equation. (4 & 5) can be used to define the width of final achieved hydrophilic channel for producing an accurate microfluidic device in the paper.

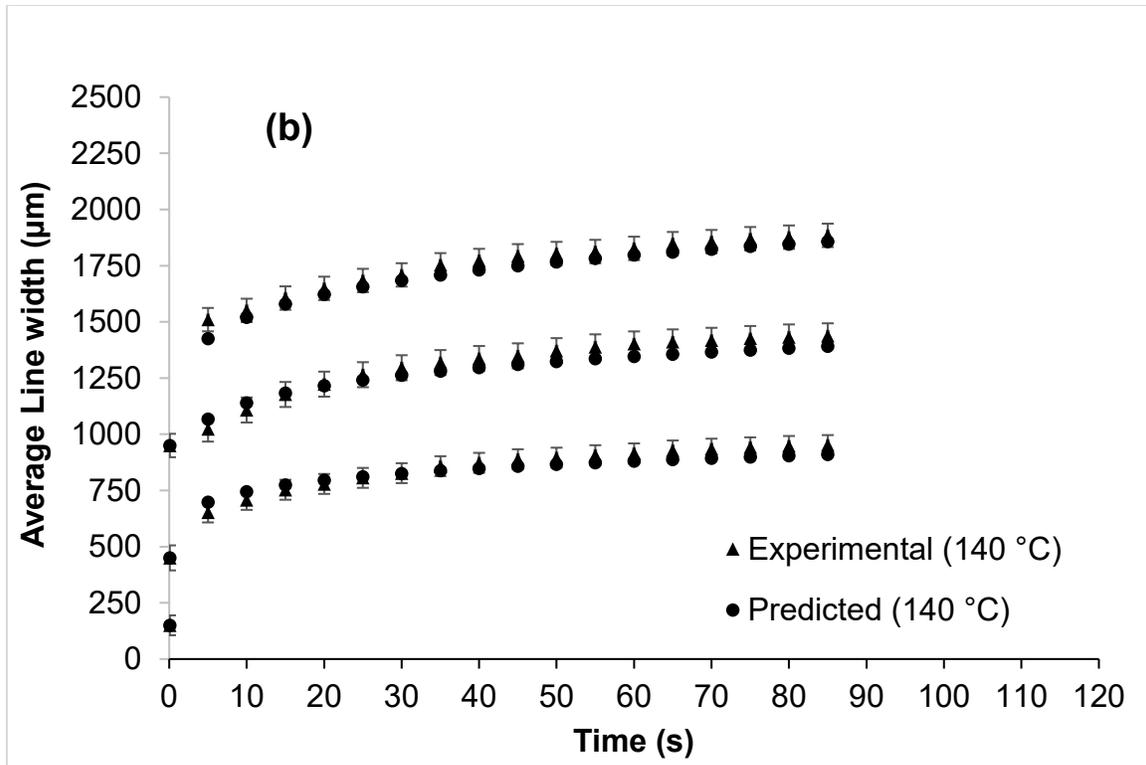

Fig. 10 Graphs showing experimental and predicted trend lines (a) at temperature 120 °C and (b) at temperature 140 °C. The error bar shows standard deviation final width of three repetitions.

The variations in the trend lines for both the experimental and predicted values can be explained by the complexity of the porous paper involved, the temperature and initial line thickness effect.

The above-developed model is also helpful in predicting the dimension of the wax barrier and channel in applications where high-density features are preferred. The final spreading of the wax line predicted in equation (3) helps the user to change the initial design for maintaining the minimum gap required between the adjacent features to avoid overlap of the final barriers after spreading.

The minimum printed line that produced a functional μ PAD had initial printed width of 300 μm resulting an average final line width of 1200 μm . Although, printer can print minimum line width as small as 50 μm but the complex nature of the paper material and the spreading phenomenon limits the minimum functional feature size that can be obtained. Series of circles printed with width ranging from 200 μm to 900 μm to check the minimum size of the printed line that result in a functional microfluidic device. Line width less than 300 μm resulted in leakage of the fluid (dye colorant) shown in Figure 11.

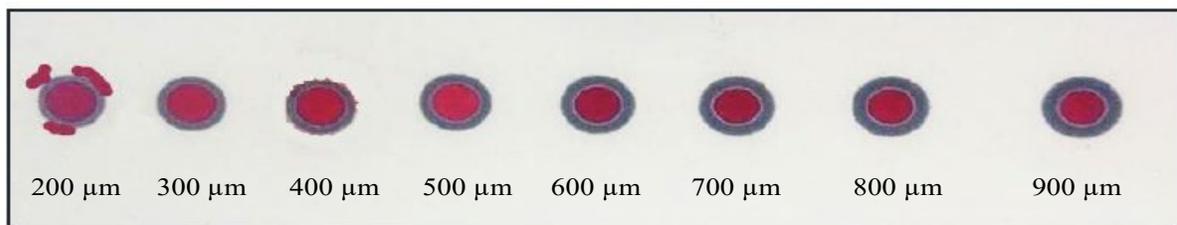

Fig. 11 Sequential increase in line width (200 μm to 900 μm). 300 μm is the the smallest printed line width resulting in a functional μ PAD

3.3 Preparation of the device for milk adulteration analysis

Printed-paper was placed on a hot plate set at 150 °C for two to three minutes. This allows the wax to penetrate well throughout the depth of paper. Optimal results were achieved by flipping the paper five to six times over hot plate. The device fabricated for milk adulteration used the best parameters (Temperature 150 °C and initial printed line 900 μm) that results in a functional μPAD. Equation 3, 4 and 5 were used to predict the width of the hydrophilic channel and wax spreading in the paper. The device comprised of a straight central channel that was divided into three independent test zones. Unique reagents were deposited at all test zones and then dried before the device was ready to use. The volume of the reagents was in the range 0.5-1 μL, depending on the size of each test zone. Sample was applied using micropipette (0-20 μL) at the starting point of the central channel. The volume of the sample was 10 μL, flowed by the device into three independent test zones through capillarity. Deposited reagents reacted with sample based on specific chemical reactions. The results were based on easily distinguishable visual colors. After drying completely, the device was ready to use. Solutions for detection of neutralizers (carbonates/bicarbonates), urea and detergents are shown in Table 4.

Table. 4 Reagents for Adulterants

Adulterants	Reagents
Detergent	Bromocresol purple solution (0.5%, w/v)
Urea	DMAB Reagent (1.6%, w/v)
Carbonates/Bicarbonates	Rosolic Acid Solution (0.1%, w/v)

3.3.1 Colorimetric tests

Different milk samples of cow and buffalo milk were arbitrarily collected from various areas of Islamabad and Rawalpindi and analyzed for adulteration of neutralizers, urea and detergents. Tests were performed and visual colors (Figure 12) were observed when milk sample reacted with the different reagents in test zones. Tests were carried out for neutralizers, urea and detergents in milk samples. In order to check the functionality of device, adulterants were intentionally added to the sample. This served the purpose for control.

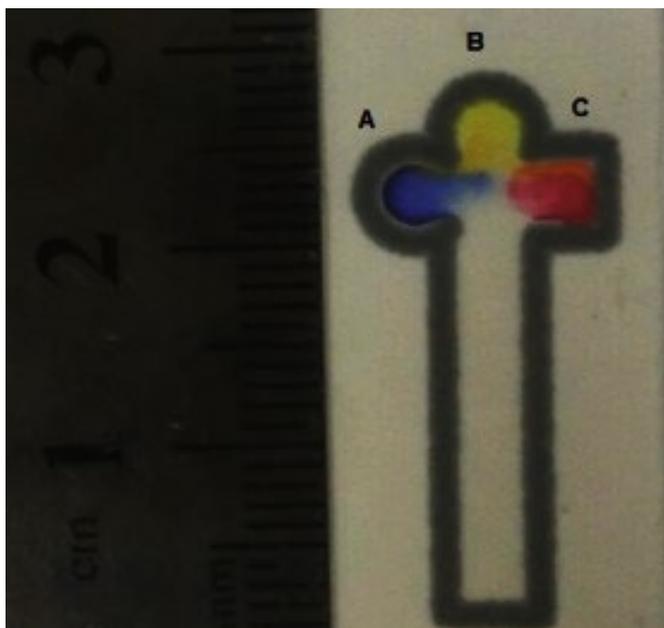

Fig. 12 Wax-printed μPAD for detecting milk adulterants with reagents deposited. Expected visual colors are shown for intentionally adulterated known sample A) Detergent B) Urea C) Carbonates/bicarbonates

Expected colors for the presence or absence of adulterants (detergent, urea, carbonates/bicarbonates) are shown in Table. 5 [27].

Table. 5 Expected colors for the presence or absence of adulterants

Tests	Adulterant/Analyte	Positive/Adulterated	Negative/Pure
A	Detergent	Purple Prominent color	Fade Violet color
B.	Urea	Distinct Yellow color	Faint Yellow color
C.	Carbonates/Bicarbonates	Rose red/Prominent Pink color	Light Brownish color

The results of different milk samples analyzed for various adulterants (detergent, urea, carbonates/bicarbonates) are indicated in Table 6. Two samples (S2 and S3) indicated sign of adulteration with detergents and neutralizers, while sample (S8) shows the presence of all these adulterants which were intentionally added to the sample. The results for sample S8 is shown in Figure 12. Others samples indicated no sign of adulteration with these adulterants (urea, detergents and neutralizers).

Table. 6 Analysis of different milk samples for various adulterants (detergent, urea and neutralizers), '+' indicates the presence while '-' shows the absence of particular adulterant in different samples.

Samples	Detergent	Urea	Neutralizers (Carbonates/Bicarbonates)
S1	-	-	-
S2	+	-	-
S3	-	-	+
S4	-	-	-
S5	-	-	-
S6	-	-	-
S7	-	-	-

S9	-	-	-
S10	-	-	-
S11	-	-	-
S12	-	-	-

3.3.2 Discussion on milk adulteration

The present study is conducted to design and demonstrate a reliable paper-based microfluidic method for analysis of milk adulteration. Quality of milk is reduced by the addition of adulterants making it potentially unhealthy for consumption. This is particularly important for neonates and especially in the first few years of children when their immune system is still vulnerable. Hence, quality control tests for milk are very important to qualify the adulteration in milk and to ensure its safe consumption [27]. Milk adulteration is prohibited because of its adverse effects [30]. A chemical fertilizer, urea, is commonly used milk adulterant. It is added to the diluted milk in order to make up the lactometer reading (density) [27]. It is often used for whitening of milk [31], causing damage to heart, kidneys and liver [32]. As it is the significant component of synthetic milk, therefore, it is added to milk for promoting its SNF (solid-not-fat) value. It is also used to increase the shelf-life of milk [32]. There are many methods for the detection of adulterated milk with added urea. Naturally, urea is also present in milk. Cow milk contains about 50 mg/100 ml of natural urea on average, however, 35 mg/100 ml (average) of urea is present in buffalo milk [27]. The detection limit for detecting added urea is 0.2% [33].

Common neutralizers like carbonates (Na_2CO_3) and bicarbonates (NaHCO_3) are used to adulterate milk for neutralizing the appeared acidity in the milk [34]. These cause diarrhea, colon ulcers and gastric ulcers [35]. The detection limit for carbonates is 0.1% and 0.2% for bicarbonates is [34]. Some neutralizers are also components of detergents [27].

Pure milk has an excessive nutritional value. It contains significant amount of essential nutrients like proteins, carbohydrates, fats, vitamins and minerals [36]. Tragically, milk consumed by most of the people of Pakistan contains adulterants [37]. Milk dealers adulterate milk by diluting it with water and adding cheap substances in order to sustain its compositional parameters. Common adulterants include unhygienic water, starch, urea, detergents and carbonates etc., [38]. “ Water, often added to dilute the milks, is obtained from unhealthy sources that may include some or all of above mentioned adulterants [39].

Among various samples tested for adulteration three samples (S2, S3 and S8) were positive (+) for adulterants. S2 was positive (+) for detergent and S3 contained neutralizers. All other samples indicated no sign of adulteration with urea, detergents and neutralizers. S8 revealed the presence of all the adulterants (intentionally added).

These devices are although reliable but can only provide qualitative analysis i.e. ‘Yes/No’ type of results. Because of the different ambient light condition and the wet or dry condition of paper, the colorimetric result may be interpreted different by different individuals as the colour and intensity interpretation by eye is different for each person. More investigation will be done in future to study the chemical reaction as well as modification in the shape of device to perform longer experiments without contaminating the samples.

4 Conclusions

In this research a regression model for accurate prediction of final dimensions of lines/hydrophobic: hydrophilic channels has been developed for paper based microfluidic devices. Experimental results show that this model is in agreement with empirical observations within an accuracy of 92 %. . Determination of line width and hence exact channel size of the final paper microfluidics devices can also help predict exact amount of reagents needed for microfluidic application. This can prevent waste of expensive reagents. This model will be very helpful in future, for mass-producing paper-based analytical wherein we can pre-calculate the desired dimension of the channels and barriers suited best to our desired applications. Finally, our results for milk adulteration tests on μ PAD depict that colorimetric reactions can easily be done on μ PADs and several independent reactions can be done simultaneously in various test zones on a device without cross-contamination of the reagents. Visualization of distinct colors on device depends on the presence or absence of adulterants.

Conflict of Interests

The authors declare that there is no conflict of interests regarding the publication of this paper.
